Tel: Fax: toms. Home monitoring of blood glucose concentrations is economically impracticable for most patients, but easier access to urine dipsticks would probably increase patients' interest and motivation in improved control and would not add greatly to total direct costs.

The need for inpatient admission should also be considered carefully, especially for newly presenting patients. Wherever possible admission is best avoided if the patient and family are able to receive initial daily outpatient education and supervision.15 Patients should be admitted only if they require nursing care or circumstances do not permit easy attendance at outpatient clinics. Admission rates for diabetic patients in Tanzania are six times higher than in the general population." When patients are admitted careful consideration should be given to the need for investigations. Testing urine four times or more daily for example, may be unnecessary if blood glucose concentrations are also being measured. Consideration should also be given to the period of admission since patients are often kept in the wards until most urine results are glucose free.

The small proportion of direct costs due to nurses' and doctors' services reflects the low rates of pay of medical staff in most sub-Saharan countries. A lecturer in medicine, for example, is paid \$60 monthly. The reasons for such low rate of remuneration are understood, but attention must also be paid to this problem since the motivation and interest of those caring for patients can have a significant impact on the quality of

Hyponatraemia and death or permanent brain damage in healthy children

Allen I Arieff, J Carlos Ayus, Cosmo L Fraser

Abstract

京药键: 3 年级131

Objective-To determine if hyponatraemia causes permanent brain damage in healthy children and, if so, if the disorder is primarily limited to females, as occurs in adults.

Design-Prospective clinical case study of 16 affected children and a review of 24412 consecutive surgical admissions at one medical centre.

Patients-16 children (nine male, seven female; age 7 (SD 5) years) with generally minor illness were electively hospitalised for primary care. Consultation was obtained for the combination of respiratory arrest with symptomatic hyponatraemia (serum sodium concentration ≤128 mmol/l).

Main outcome measures-Presence, gender distribution, and classification of permanent brain damage in children with symptomatic hyponatraemia in both prospective and retrospective studies.

Results-By retrospective evaluation the incidence of postoperative hyponatraemia among 24412 patients was 0.34% (83 cases) and mortality of those afflicted was 8.4% (seven deaths). In the prospective population the serum sodium concentration on admission was 138 (SD 2) mmol/l. From three to 120 inpatient hours after hypotonic fluid administration patients developed progressive lethargy, headache, nausea, and emesis with an explosive onset ofrespiratory arrest. At the time serum sodium concentration was 115 (7) mmol/l and arterial oxygen tension 6 (1.5) kPa. The hyponatraemia was primarily caused by extrarenal loss of electrolytes with replacement by hypotonic fluids. All 16 patients had

cerebral oedema detected at either radiological postmortem examination. All 15 patients not treat for their hyponatraemia in a timely manner eith died or were permanently incapacitated by bra damage. The only patient treated in a time manner was alive but mentally retarded.

Conclusions-Symptomatic hyponatraemia c result in a high morbidity in children of both gender which is due in large part to inadequate bra adaptation and lack of timely treatment.

Introduction

In previous studies from our laboratories we ha described the symptomatology, clinical course, effec of treaument, and pathological findings in more th 225 adults (aged over 16) with symptomatic hyp natraemia.14 Although the actual incidence of hyp natraemia seems to be similar among men 21 women," almost all adult patients suffering hyp natraemic brain damage are women. Although the are a number of reported paediatric cases of byp natraemia, 10-12 there are few reported cases of death permanent brain damage among children with th disorder," and most such children had pre-existing neurological disorders.1517 Neither the gender dista bution nor the incidence of brain damage amor children with hyponatraemia is known. 16 13-47 Amor children suffering brain damage from hyponatraem neither the type nor the gender distribution is known We describe both a prospective and a retrospective analysis of generally healthy children who were elec-

ively hospitalised. Sixteen children who developed severe symptomatic hyponatraemia either died or suffered permanent brain damage. Unlike the situation in adults, both males and females were adversely affected among these children.

Patients and methods

Prospective studies—Over a period of six years (1984-90) we were consulted about 16 previously healthy children (aged under 16) who had developed symptomatic hyponatraemia and either died or suffered permanent brain damage. These 16 patients were seen in consultation from five tertiary and nine community hospitals. The age of the children was 7 (SD 5) years (range 1.5 to 15 years), and the gender distribution was nine males and seven females. The mean weight was 23.8 (12.9) kg (range 10 to 52 kg). Symptomatic hyponatraemia developed within five days of admission to the hospital.

Epidemiological studies—We retrospectively studied all surgical admissions to a 456 bed tertiary paediatric university teaching hospital over three years (1989-91). The records of all paediatric (age under 16) surgical patients were evaluated for those who had postoperative hyponatraemia (serum sodium concentration 128 mmol/l or less) and the number who either died or suffered permanent brain damage as a result of the hyponatraemia. The epidemiological data were generated by computer search of the hospital records using the SAS database" to obtain information on all paediatric surgical patients who had a postoperative serum socium concentration of 128 mmol/l or less. There were 24412 consecutive inpatient operations over the venous fluids per kg daily. Urine output was 34 (34) ml/ three years ended 31 December 1991. In addition, we-kg per day and other fluid losses averaged 28 (25) ml/kg calculated an approximation of the incidence of hypo-per day (nasogastric suction, n=2; emesis, n=10; natraemic brain damage in children in the United cerebrospinal fluid drainage, n=1; not charted, n=3) States from our epidemiological data plus a statistical a with mean net output of 74 (82) rul/kg daily and net database from the medical literature."3

Results STUDY PATIENTS

The table shows the clinical circumstances which resulted in hospitalisation of the 16 patients. All data

are presented as means (SD). Symptoms were not known in three patients, who were either too young (less than 18 months) or intubated and thus unable to vocalise any complaints. Of the remaining 13 patients, 11 had progressive lethargy, weakness, nausea, and emesis and 12 had headache. All patients suffered respiratory arrest after a mean of 37 hours (range three to 120 hours) from the start of intravenous fluid administration.

CLINICAL COURSE

At admission the serum sodium concentration was 138 (2) mmol/l. As early as two hours after starting hypotonic fluid administration those patients able to communicate became progressively more lethargic and complained of headache and nausea, with subsequent emesis. All such symptoms were generally unresponsive to conventional agents (phenothiazines and narcotics). After a mean of 37 hours all 16 patients suffered respiratory arrest, at which time the serum sodium concentration was 115 (7) mmol/l and urine osmolality 676 (66) mmol/kg. This level of urine hypertonicity in the presence of hyponatraemia suggests that the plasma antidiuretic hormone concentration was raised." The onset of respiratory arrest was often explosive in nature, and hyponatraemia was generally not considered as a possible cause.

Immediately after respiratory arrest but before oxygen administration or intubation the arterial oxygen tension was evaluated in 11 patients and was 6.0 (1.5) kPa. During the 37 hours between the time of admission and onset of respiratory arrest the patients had received a mean of 125 (83) ml hypotonic intrapositive fluid balance of only 27 (14) ml/kg per day. Hyponatraemia in these children was thus largely due to extensive extrarenal loss of electrolyte containing fluids with replacement by hypotonic fluids. Most of the intravenous fluids were administered as 280 mmol glucose per litre either in water or in sodium chloride 38 mmol/l, but the plasma glucose concentration was

subsequently developed the syndrome of central diabetes mellitus and central diabetes insipidus' with hypotonic polyuria. In these four patients the mean serum sodium concentration rose (without treatment) from 114 (6) mmol/l to 164 mmol/l and the glucose concentration to 31-1 mmol/l. None of these patients had been treated for their hyponatraemia.

OUTCOME

All 16 patients either died or suffered permanent brain damage (table): one was mentally retarded, 10 died, and five were in a persistent vegetative state which persisted for follow up intervals of at least two years. Twelve patients received no specific treatment for their hyponatraemia. Of these, nine died and three remained in a persistent vegetative state.2 Four patients were eventually treated with intravenous sodium chioride 154 and 514 mmol/l (table) such that the serum sodium concentration was increased from 108 (9) to 138 (4) mmol/l in 44 hours. The average delay from respiratory arrest to start of treatment was eight hours, all four patients were comatose, apnocic, and intubated at the time treatment was begun, and none awoke either during treatment or for three days thereafter. Only one patient (case 6), who survived mentally retarded, was treated within 10 minutes of respiratory arrest.

NECROPSY FINDINGS

Postmorten examination of the brain was performed in 10 patients (three girls, seven boys). In nine patients who had received no treatment and died in less than 48 children; p<0.01)33 or diuretic induced hours there was cerebral oedema and herniation on a cations. 242 It is important to recognise that in c gross examination of the brain. The brain weight when there is substantial extrarenal loss of elec (unfixed) in six patients (three male, three female) a minimal positive balance of hypotonic fluid
whose mean age was 3-8 years was 1354 (95) e For to foral hypotonic fluid whose mean age was 3-8 years was 1354 (95) g. For to fatal hyponatraemia. Another major facto comparison, the normal brain weight in men is 1450 g, may have contributed to the high morbidity in women 1250 g, in 4-5 year old boys 1300 g, and in these children was the virtual absence of 4-5 year old girls 1150 g.3 Thus brain weight was treatment in the presence of obvious symptom increased by more than 10% above control values for Furthermore, the types of operations and the children of the age range studied. That transtentorial conditions in this patient population were si herniation was present in all nine patients subjected to postmortem evaluation correlates well with the observation that the human brain can expand by only about 5-7% of its normal volume before herniation occurs. We have shown that men's brains can usually adapt to hyponatraemia within a few hours whereas women's brains may not adapt within several days." In all 16 children presented here the brains were unable adequately to adapt to hyponatraemia.

EPIDEMIOLOGICAL FINDINGS

Among 24412 paediatric surgical admissions to a 456 bed university paediatric hospital there were 83 (0.34%) patients who developed hyponatraemia. Among these, seven (8.4%) died of complications of the hyponatraemia. Among the seven deaths, four were in boys and three in girls. Hence the incidence was 340 cases of paediatric postoperative hyponatraemia and 29 hyponatraemic deaths per 100 000 inpatient operations on children. There are 2.02 million paediatric inpatient operations a year in the United States." The estimated yearly incidence in the United States is 7448 cases of paediatric postoperative hyponatraemia, with 626 such hyponatraemic deaths in children. The most common inpatient operations on children in the United States" are to the nose, mouth, and pharynx (17%); digestive system (17%); musculoskeletal system (15%); and nervous system (13%), of which 43% are performed in girls. This was essentially the distribution in our series, in which 92% of operations were in these four groups and 44% of the patients were female (table).

ance cases since that benerally licality with symptomatic hyponatraemia (101-123 can abruptly develop respiratory arrest and e or develop permanent brain damage. The pe brain damage can include pituitary infarct resultant central diabetes insipidus and me syndrome not previously described in childr incidence of postoperative hyponatraemia in (0-34%) was less than in adults (1-4%). 121 H among paediatric patients who developed symhyponatraemia the incidence of permaner damage was substantially higher than in a Both the types of surgery and gender dist among our 16 patients (table) were the same as common operations and gender distribution United States as a whole," and thus our 16 were representative of the spectrum of elective tric surgical patients.

The hyponatraemia in these children seem: been caused by extensive extrarenal loss of ele containing fluids and intravenous replaceme hypotonic fluids (table) in the presence of ant hormone activity. Increased plasma concentra antidiuretic hormone are usually found in bo ren and adults with hyponatraemia, 11-14 16 28 hormone has multiple cerebral and vascula which can impair the ability of the brain to hyponatraemia." However, the genesis c natraemia in children is usually different from adults. In adults there has often been administ very large quantities of intravenous fluid (net r 63 ml/kg per day in adults v 28 ml/kg per those most common in the United States." I index of suspicion for electrolyte disorders in g healthy children undergoing elective surgery quite low.

BRAIN ADAPTATION TO HYPONATRAEMIA IN CHII

In adults oestrogens seem to impair the abili brain to adapt to hyponatraemia and androgaugment such adaptation." However, prept children have only minimal to absent concentreither hormone, thus negating such effect adults suffering permanent brain damage from natraemia are female,3378 but in the current minority of affected patients (43%) in both t pective and retrospective studies were femal unlike the marked gender differential in adul and female children seem to be at similar developing hyponatraemia encephalopathy test)). Furthermore, neither the actual conce of serum sodium nor the rapidity of develop hyponatraemia seemed to predict the ultimate in these 16 children (table). Hyponatraemia de over a mean of 37 hours and the range of serur: values was 101-123 mmol/l, values quite si. those previously reported in children with matic hyponatraemia who did not develo damage.16 12 13 14

EFFECTS OF PHYSICAL FACTORS

When hyponatraemia was present all 16 had radiological evidence (computed tome magnetic resonance imaging) of cerebral

whereas at necropsy nine of 10 evaluated had cerebral oedema with herniation. These findings show that adequate adaptation of the brain to hyponatraemia had not occurred. There are several unique characteristics of the paediatric central nervous system which may impair the ability to adapt to hyponatraemia. Such characteristics may include physical factors resulting from differences in the ratio of intracranial capacity to brain size, cerebrospinal fluid volume, and brain water and electrolyte content.

The early adaptation of brain to hyponatraemia involves a loss of blood and cerebrospinal fluid followed by extrusion of sodium from brain cells." B Later adaptation includes loss of potassium and possibly amino acids, which act further to decrease brain cell osmolality and limit the gain of water.14 In humans and laboratory animals brain water content is more than 2.5 times higher in the young, decreasing progressively with age. ** In children the ratio of brain to skull size is such that there is less room for expansion of the paediatric brain in the skull than there is in adults." As adults age there is a progressive decline in the brain volume whereas skull size remains constant." Hence anatomically there is decreased room for expansion of the brain within the skull in children as compared with adults.33

Adult brain size is reached at about age 6 whereas full skull size is not reached until age 16. Additionally, the intracerebral volume of cerebrospinal fluid is more than 10% greater in adults than in the young." When brain swelling occurs the intracerebral loss of cerebrospinal fluid increases the available volume in which the spinal fluid in the brain increases with age. adults of 4 Ayus JC, Krothapali RK, Aniell Al. Treament of symptomatic bypomatic brain can expand. " As the percentage of cerebroboth genders have more room in the rigid skull for the brain to expand than do children. Furthermore, the brain intracellular concentration of sodium is about 27% higher in children than in adults and may reflect a relative decreased ability to pump sodium out of the brain in children. In the presence of hyponatraemia this will result in a greater osmolar gap between brain and plasma in the young. It has been shown that in newborn puppies with hyponatraemia the brain is unable to extrude cations" whereas adult animals with hyponatraemia can readily transport sodium out of the brain.13134

PREVENTION AND TREATMENT OF HYPONATRAEMIC **ENCEPHALOPATHY**

Symptomatic hyponatraemia can best be prevented by not infusing hypotonic fluids to hospitalised children unless there is a clear cut indication for their use. Headache, nausea, emesis, weakness, and lethargy are consistent symptoms of hyponatraemia in children. If the condition is allowed to go untreated there can follow an explosive onset of respiratory arrest, coma, and transtentorial cerebral herniation. At present there is no way to predict which children may suffer respiratory arrest. As found recently in adults neither the magnitude of hyponatraemia nor its duration is the major determinant of brain damage.* Recent studies show that recovery from symptomatic hyponatraemia in children, even after the onset of seizures and apnoea, may be possible if appropriate treatment is instituted in a timely manner."

When a paediatric patient receiving hypotonic fluids begins to have headache, emesis, nausea, or lethargy the serum sodium concentration must be measured. Although these symptoms are somewhat non-specific, the diagnosis is easily established at minimal cost and with virtually no risk to the patient by evaluating plasma electrolyte values. When symptomatic hyponatraemia is diagnosed the patient should be moved to a location where constant monitoring can be provided, such as the intensive therapy unit. Hypertonic sodium

chloride (514 mmol/l) should be infused as cribed,41141 such that the serum sodium concenti is increased to 125-130 mmol/l but by no more th mmol in the initial 48 hours. In addition to hyper sodium chloride, treatment may include intul and assisted mechanical ventilation when require

We thank Anne Ludvik and Trish Sullivan, library service at the San Francisco Veterans Affairs M. Center, for help in preparing the database and the me records department of the Children's Hospital, Hot Texas, for help in preparing the statistical data.

Addendum

After submission of this paper a report appeared descr 34 paediatric patients with water intoxication.4 Two c patients became hyponatraemic secondary to intrave hypotonic fluid administration (serum sodium concentra 112 and 114 mmol/l). Both suffered respiratory arrest died, and at necropsy both had cerebral oedema. These patients had a clinical course similar to the 16 in our se The other 32 patients had oral water interication, an survived because of timely and appropriate treatment.

First use of heroin: changes in route of administration over time

John Strang, Paul Griffiths, Beverly Powis, Michael Gossop

AIDS and drug misuse are linked mainly by the injection of many drugs. Major changes in the methods of heroin use, however, have fundamentally altered the importance of heroin use in the transmission of HIV. Recent reports describe the extent of "chasing the dragon" (inhaling sublimated heroin after heating it on rinfoil) as a new route of heroin use but give no information on the emergence of this pattern.12 During the 1960s heroin use was by injecting. What events occurred (and when) to account for this substantial change in the nature and the link with HIV of the beroin epidemic?

Subjects, methods, and results

Four hundred heroin users were contacted and interviewed by trained peer group interviewers through a structured and tape recorded interview. A total of 204 (51%) were currently out of contact with any treatment service, 100 (25%) were currently attending a drug

Initial rouse of heroin use

clinic, and 124 (31%) were currently attending a needle exchange scheme. A total of 136 (34%) had never had contact with either treatment services or an exchange scheme. Their ages ranged from 17 to 53 (mean (SD) 27-6 (6-3) years); 248 (62%) were male; 96 (24%) were in current employment. There was wide variation in first year of use of heroin use (1954 to 1991): 16 (4%) started during the '60s, 28 (7%) during the early '70s, 76 (19%) during the late '70s', 124 (31%) during the early '80s, 120 (30%) during the late '80s, and 36 (9%) during the '90s.

Three different routes of initial drug use were identified: injecting, snorting, and "chasing the dragon." Analysis of these data by year revealed a major change in the annual proportion who were initiated by either injecting or chasing (figure).

Chasing" was a route of initiation for a minority of users up to the late 1970s but has become an increasingly common route of initiation since 1975. By 1979 there were as many initiations by chasing as by injecting, and by 1981 more than half of the initiations into heroin use were by chasing (with the annual proportion remaining above half since 1981). By 1985 more than three quarters of initiations were by chasing, and since 1988, 87 out of 93 initiations (94%) were by chasing. During most years, a tenth to a quarter of users were initiated by snorting.

Comment

Heroin use today is not what it was yesterday. Initiation no longer occurs by injecting but by the new route of "chasing the dragon." The emergence of new non-injecting routes of heroin use may partly explain not only the major heroin epidemic in the United Kingdom during the 1980s but also its apparent continuation despite the addition of AIDS as a potential consequence. Perhaps the protective societal taboo against injecting was circumvented and a less fettered epidemic has developed. In the 1990s virtually all initiations into heroin use in our London sample were by "chasing the dragon," even though heroin use in other countries (for example, the United States) and even in other British cities (for example, Edinburgh) continues to be by injection. Should the change in London be regarded as an isolated development in a few "chasing" cities, or is it an indication of likely future changes on a wider scale? And what is the significance for tomorrow's prevention and treatmen brodrammer;

Our level of ignorance about changing routes of drug administration is not only scientifically disturbing bu also interferes with the development of prevention and treatment programmes. Effective primary prevention strategies depend greatly on the adequacy of knowledge about the gateways into drug use, and yet our understanding of the phenomenon is informed largely by
